57) A cryptographic system allows, in one exemplary use, a supplier (101) to cryptographically transform a plurality of messages responsive to secret keys; the transformed messages to be digitally signed by a signer (102); and the signed transformed messages returned to the supplier (101) to be transformed by the supplier (101), responsive to the same secret keys, in such a way that a digital signature related to each original message is developed by the supplier (101). One important property of these systems is that the signer (102) can not determine which transformed message received for signing corresponds with which digital signature—even though the signer (102) knows that such a correspondence must exist.

FIGURE 1

BLIND SIGNATURE SYSTEMS

BACKGROUND OF THE INVENTION

1. Field of the Invention.

This invention relates to cryptographic systems, and more
5 specifically to systems including public key digital signatures.

2. Description of Prior Art.

The concept of digital signatures promises to be an important
one in commercial applications of cryptographic techniques. The
digital signatures concept is quite simple. Suppose a bank wishes
10 to be able to make digital signatures that can be checked by all its
customers. The bank develops a mathematical function, and supplies
all its customers, and anyone else who cares to know, complete
instructions for efficiently computing the function. The trick is,
that when the bank developed the function, it included in it a trap-
15 door. This trapdoor allows the bank to efficiently compute the
inverse of the function. Because it is infeasible to compute the
inverse of the function without knowing the trapdoor, only the bank
can compute the inverse of the function. Thus, if a customer of the
bank sees a message that could only have been created by someone who
20 knows how to compute the inverse of the function, then the cus-
tomer knows that the message must have come from the bank.

The concept of digital signatures was first proposed in the
literature by Diffie, et al, in "Multiuser Cryptographic Tech-
niques," AFIPS--Conference Proceedings, Vol, 45, pp. 109-112. The
25 first really practical example functions with the required trapdoor
properties were disclosed by Rivest, Shamir and Adleman, in "A
Method for Obtaining Digital Signatures and Public-Key Cryptosys-
tems," Communications of the ACM, Vol. 21, No. 2, February 1978.

- 2 -

This system has become known as "RSA", after its inventors, and remains the most credible candidate for widespread use. It is based on two main ideas. The first is that is relatively easy for someone to create a large number for which only he knows the prime factors.

- 5 (One way to accomplish this is for the creator to form the number as the product of two suitable sufficiently large primes chosen at random. Such primes are easily found by random trial and error since the density of primes even in the neighborhood of 50 digit numbers is on the order of one percent, and reasonably efficient primality
10 tests are well known in the art.) The second main idea is that knowing the prime factors of the modulus under which exponentiation is performed allows one to produce pairs of exponents that behave as inverses.

- In other words, consider the function $f(x) = x^e \bmod n$, to be the
15 result of raising x to the power e and then finding the remainder after dividing by n . There may be a number d , such that
 $g(x) = x^d \bmod n$ and $g(f(x)) = f(g(x)) = x$. If one chooses primes p and q and a suitable e , one can readily compute a corresponding d , simply as the multiplicative inverse of e modulo $((p-1) \cdot (q-1))$,
20 such modular multiplicative inverses to be described. It is thought to be almost impossible to compute d from e and n without knowing p and q , and almost impossible to determine p and q from n . Thus, if e and n are made public, anyone can compute $f(x)$, but only the creator of n can compute the inverse $g(x)$.

- 25 There are a variety of ways to use such a "public signature function" and its inverse "secret signature function" to make digital signatures. In general, it is not desirable to maintain that any message which results from applying the public signature function is a valid signed message. The reason is that anyone could
30 create a number at random and claim that it was a signature on the message that results when the public signature function is applied. One solution to this problem is to designate some sub-set of the messages as "valid messages" such that, for example, only one in

- 3 -

10⁵⁰ messages is valid. Thus someone would have to apply the public signature function to an average of $5 \cdot 10^{49}$ random messages, (which may not be a credible threat) before obtaining a valid message as a result. (An RSA system with a one-hundred digit modulus would still
5 have 10⁵⁰ possible valid messages.) The process of "checking" a digital signature in such a scheme involves applying the public signature function to the digital signature to be checked, and determining whether the resulting number is a member of the set of valid messages.

10 It is anticipated that a bank may wish to use digital signatures to validate various numbers that are to serve as electronic money. The bank will form digital signatures of valid numbers, and sell them to individuals by charging the individuals' accounts say one dollar for each signed number. These digitally signed numbers
15 might be thought of as electronic bank "notes". An individual can check the digital signature on such a digitally signed note by applying the public signature function of the bank to the note and verifying that the result is a valid message. When the individual wishes to pay for some goods or services, say for example, buying
20 something costing one dollar at a shop, the individual gives the digitally signed note to the shop as payment. The shop can then check the digital signature on the note. If the result of the check is positive, then the shop can supply the digital signature to the bank, who can deposit one dollar in the shop's account, after again
25 checking the signature on the note. The bank will also keep a list of the valid numbers which have been previously cleared, to prevent the same one from being used more than once. Of course, many different denominations of such digitally signed bank notes might actually be offered for sale by the bank, each denomination using a dif-
30 ferent pair of signature functions.

The problem with such payments systems possible under the prior art is that the bank will always be able to know which account a note was withdrawn from and which account it is ultimately deposited

to--and this poses serious problems from a personal privacy perspective. As more and more payments transactions become automated, and more and more data associated with transactions is captured electronically, a tremendous amount of data about a person's habits, 5 affiliations, lifestyle, whereabouts etc. could be captured by the bank in electronic form. This places the bank in a position it would rather not be in, because it has to convince its customers that it handles this data properly, and also because of possible legal exposure, there will be various costs, restrictions on and 10 interference with operating procedures and personnel. The customers of the bank are also placed in an undesirable position, since there may always be some doubt as to how such data is actually being used or might be used in the future.

This examples illustrates the need for signature systems that 15 do not allow the signer to trace all things validated with his signature. Many other similar situations, such as, notaries, stock, bond, and other certificates, credentials, authorizations etc. are also anticipated.

OBJECTS OF THE INVENTION

20 Accordingly, it is an object of the present invention to provide a system utilizing digital signatures in which the provider of a message for signing can transform the message to be signed into a form which obscures the content of the message, the signer can sign the transformed message and return it to the provider, and the pro- 25 vider can transform the signed message in such a way that the result retains the digital signature property related to the original message content, but the result is not readily associated with the transformed message received by the signer.

Another object of the present invention is to provide a system 30 which can be used in a payments or other type of system as

previously described, wherein, for example, the provider may choose a valid bank note message at random, transform it, have it signed in transformed form, and transform it back to a form related to the original note but bearing a digital signature property.

5 Another object of the invention is to provide a system with the additional property that the security of the system against linking of the transformed messages received by the signer with the signed messages ultimately revealed by the provider does not rely on arguments based on computational infeasibility.

10 Another object of the invention is to provide additionally the property that if only j things are signed, then no more than j signatures can be developed by the provider(s).

15 Yet another object of the invention is to allow messages to be transferred through what might be thought of as a series of more than one provider on the way to the signer and return through a related series of providers.

Still another object of the invention is to provide efficient, economical and practical apparatus and methods fulfilling the other objects of the invention.

20 Other objects, features, and advantages of the present invention will be appreciated when the present description and appended claims are read in conjunction with the drawing figures.

BRIEF DESCRIPTION OF THE DRAWINGS

25 FIG. 1 shows a combination functional and detailed block diagram of a blind signature system in accordance with the teachings of the present invention.

FIG. 2a shows a block diagram of a single provider use in

- 6 -

accordance with the teachings of the present invention.

FIG. 2b shows a block diagram of a first two provider use in accordance with the teachings of the present invention.

FIG. 2c shows a block diagram of a second two provider use in
5 accordance with the teachings of the present invention.

FIG. 3 is a detailed schematic diagram of an exemplary embodiment of a modular inverter.

FIG. 4 is a detailed schematic diagram of an exemplary embodiment of a modular exponentiator.

10 FIG. 5 is a detailed schematic diagram of an exemplary embodiment of a modular multiplier.

FIG. 6 is a detailed schematic diagram of an exemplary embodiment of a modular subtractor.

FIG. 7 is a detailed schematic diagram of an exemplary embodiment of a modular adder.
15

BRIEF SUMMARY OF THE INVENTION

In accordance with these and other objects of the present invention, a brief summary of an exemplary embodiment is presented. The concept of blind signatures may be understood by an analogy
20 based on carbon paper lined envelopes. Suppose Alice supplies Bob with a first envelope and a second envelope, each containing a piece of carbon paper facing a blank white slip of paper. Bob signs both envelopes on the outside with identical signatures and returns them to Alice. Alice privately removes the paper slips from the
25 envelopes, each slip now bearing a carbon image of Bob's signature; places the slips in a random order; presents them to Bob; and asks him which slip was in the first envelope. Bob can not answer with

certainty, though he knows each slip was in an envelope he signed, because he does not know which slip was in which envelope.

Turning now to FIG. 2a, one exemplary embodiment will be described in simplified form to introduce some central concepts, but
5 such description should not be taken to limit the scope of the invention, which is described more fully elsewhere in the present specification. Two cryptographic transformations, "blinding" 203 and "unblinding" 204, are shown depending on a secret cryptographic key k . A digital signature transformation 202 is shown, which
10 depends of secret signing information not shown for clarity.

The original message m (corresponding to the blank slip of paper in the analogy above) is first encrypted by blinding transformation 203 (which corresponds with placing the slip in the special envelope), resulting in transformed message t (corresponding to the
15 slip in the envelope). A digital signature responsive to the transformed message t is then developed by signing transformation 202 (corresponding with Bob signing the outside of the envelope), and is shown as t' (corresponding to the signed envelope). The unblinding transformation 204 takes t' and converts it, by use of
20 key k into a variant m' of the original message m which retains a signature property (corresponding to the signed slip removed from the envelope by the party who placed it there).

This entire procedure would normally be repeated more than once, say l times, using a fresh key k_j , $1 \leq j \leq l$, each time (just as
25 there were multiple envelopes in the analogy). Thus, a set of signed values $\{m'_j\}$ are generated (corresponding to a set of signed slips), as well as a set of transformed values $\{t_j\}$ (corresponding to a set of envelopes). An important property of such a blind signature system is that if the signer knows only the two unordered
30 sets, and not the keys k_j , then the signer is unable to readily determine the correspondence between the elements of the two sets (just as Bob was unable to tell which slip was from which

- 8 -

envelope)--even though the signer is assured by the signature property that such a correspondence must exist.

In one embodiment of the present invention, based on the RSA digital signature system as earlier described, the following
5 congruences might hold:

$$t \equiv [m] \cdot k^e \pmod{n},$$

$$t' \equiv [m \cdot k^e]^d \equiv m^d \cdot k \pmod{n}, \text{ and}$$

$$m' \equiv [m^d \cdot k] \cdot k^{-1} \equiv m^d \pmod{n},$$

where n is the publicly known modulus and e and d are exemplary public and private signature exponents respectively. The square brackets show the input to the transformation whose output is shown on the right hand side, and thus they define the function of each of the three transformations. The signature property of m' might be checked by anyone with access to the public signing function based
10 on e , simply by forming $m'^e \pmod{n}$ and checking whether the result is
15 a valid message m .

GENERAL DESCRIPTION

General descriptions of the functions of some constituent parts of the present invention will be presented.

20 Line 155 shows the output of blinding transformation 103 being input to signing transformation 102; line 157 shows the output of signing transformation 102 being input to unblinding transformation 104; line 159 shows the output of unblinding transformation 104 being input to signature checker 105. The method or means whereby
25 such information is transferred as shown by these lines is not

essential to the present invention, and may be accomplished in any suitable way. For example, the output or input means may be brought into physical proximity with each other, or they may communicate remotely by any kind of communication network or other technique.

- 5 The information may be encoded in various forms, some of them cryptographic, and decoded and transformed between codings on its way. Similarly the information may be stored and/or detained in various forms along its way.

The term "party" is used herein to indicate an entity with control over some secret information. In some cases, a party might be a person who knows a secret cryptographic key. It is anticipated that a plurality of people may each know part or all of some key matter, and then they might collectively be thought of as a party. In other cases, a key may normally be known only to apparatus and not people, and the apparatus or the people able to utilize the apparatus may be regarded as parties. Different people may use the same apparatus each with different keys, assuming they all have some trust in the apparatus, and then they might be regarded as separate parties. Thus, for example, signature transformation 102 may be regarded as a step in a method or part of an apparatus, and/or it may be regarded as a party, and it may be called signer 102 or signer party 102.

Key source 123 is shown without inputs and with output 153. The function of key source 123 is to output a value normally at least partially unknown to at least the signer party 102. It is preferred that the output is nearly completely unknown outside the provider 101, and may not even be known to any persons but to only apparatus. The term "secret key" may be used herein to refer to information, such as the output of key source 123, that is normally supposed to be unknown to various parties. Many means and methods are known in the art for generating such keys. One approach uses unpredictable physical phenomena, such as noise in a semiconductor or other electronic component or radioactive decay, or timing of events generated by asynchronous processes, such as humans pushing

- 10 -

buttons. Another approach uses algorithmic transformations on other secret information. Of course these two approaches can readily be combined. The output of the key source is shown as input to transformations 103 and 104. The probability distribution of keys
5 is obviously of interest. In the preferred embodiment, they are preferably as nearly uniformly distributed as practical. The output may be generated initially for one, and then retained, possibly in encrypted form, and/or in some protected and/or tamper indicating or tamper responding apparatus. An equivalent approach for the present
10 invention would be re-generating the key algorithmically each time it is needed.

Signature checker 105 is shown taking its input from the output of unblinding transformation 104, line 159, and producing output 161, shown in the preferred embodiment as m. The function of
15 checker 105 is to produce an indication of whether the input value has the properties of a valid signature. An implicit input is the public signature information, shown as e in the preferred embodiment. The authenticity of this information forms the basis for the authenticity decision about the signature input, and thus such
20 information may be shown contained within checker 105. Checker 105 serves a logical function of indicating whether or not the signature appears to have been transformed using the secret signature information corresponding to the public signature information; any means or method performing this function may be regarded as a signature
25 checker. (Other data may also be output by the checker 105, such as parameter values included during formation of the signature.)

Various signature means and methods are known or would be obvious to those skilled in the art. One method, that of choosing a subset of the domain of the signature function as valid messages,
30 has already been described. Another approach might not make such a restriction, but might instead rely on information additional to the output of the signature function for input to the checking function. One-way functions may be thought of as public functions without publicly known inverses, such functions being well known in the art,

such as the public function of an RSA system as earlier described, or those first disclosed by Purdy in "A High Security Log-in Procedure," Communications of the ACM, Vol. 17, No. 8, August 1974, p442. Suppose the range of a one-way function $y(x)$ is the domain of
5 a private signing function $g(x)$, with public signature function inverse $f(x)$. One way to use such functions to form digital signatures is to form a signature, s , as the secret signature function of the image of the desired message, a , under the one-way function, $s = g(y(a))$. A signature can be authenticated under such a scheme
10 if numbers a and s are presented to the checker 105, such that $y(a) = f(s)$. Notice that if the domain of y is larger than its range, then it serves to compress the matter to be signed. Also notice that if the domain of y is smaller than the range of g , then all or part of the number a may be encoded as the rest of the domain
15 of g . In some cases a strict one-way property may not be required.

Signing transformation 102 outputs some transformation of its input which depends on signing information at least secret from the other parties, shown as d in the preferred embodiment. Various exemplary signing transformations have been described above, but the
20 function of the signing transformation should be regarded as any transformation at least partially responsive to the information to be signed and to secret signing information, such that some suitable checking function can be performed meaningfully. The term party, as mentioned earlier, may be used when referring to the signing
25 transformation 102, and then it would be appropriate to say signer 102.

Blinding transformation 103 takes a message from line 151, shown as m in the preferred embodiment, and a secret key from line 153. The nature of the source of m is not essential to the present
30 invention, but the particular value of m resulting in an actual particular output of blinding transformation 103 received by signer 102 should not normally be revealed to the signer 102 by such a source, as this would allow the correspondence to be learned by the signer. The function of blinding transformation 103 is to produce output

- 12 -

that does not normally reveal the actual message input to those not in possession of the secret key k , and to cooperate with the signing and unblinding transformations, as will be described. Thus, the blinding transformation may be thought of as a cryptographic transformation which hides some message by use of a key, with additional properties that allow it to cooperate with the other transformations.

Unblinding transformation 104 takes a key from line 153 and a value from the signature transformation 102 on line 157, and produces an output shown as line 159. The function of unblinding transformation 104 is to transform its input into a form which "retains a digital signature property related to original message m ". In other words, a checker 105 should be able to return a positive result when supplied output of unblinding transformation 104, and possibly other appropriate information, such result indicating that a signature related to the original message m has been authenticated.

Several possible properties of blind signature systems will be described in accordance with the teachings of the present invention.

One general property of a blind signature scheme is that the blinding transformation should make it difficult, if not impossible, to determine the message m with certainty from the transformed message t without key k . For the purposes of the present description, this property will be referred to as "hiding", and thus it may be said that the blinding transformation hides the message. In the preferred embodiment, as mentioned earlier, the blinding transformation includes multiplying modulo n by k^e . If e is non-zero and fixed and coprime with $\phi(n)$, and k is chosen from the interval 0 to $n-1$, then the signing function $g(k) \equiv k^e \pmod{n}$ is one-to-one and onto. If m is coprime with n , then $h(m) \equiv g(k) \cdot m \pmod{n}$ is one-to-one and onto. Thus, under the assumptions of proper e , and m coprime with n , a particular value of t could correspond with any value of m , with unique suitable k . In a sense then, it is believed

- 13 -

that, the security of the hiding in the blinding transformation of the preferred embodiment is comparable to that of the so called one-time pad, when $\text{GCD}(m,n) = \text{GCD}(e,\phi(n)) = 1$, and k chosen uniformly from the interval 0 to $n-1$. Of course, if e is not coprime with $\phi(n)$ then certain messages may have no signature; and if it is likely that m is not coprime with n , then it is likely that someone can guess a factor of n , or providers could use Euclid's algorithm to reject any non-coprime m .

Another property of a blind signature scheme which may be important in some anticipated applications will be called "conservation of signatures". This property requires that it not usually be easy for someone to construct a set of transformed messages such that after each member of the set is signed, more authenticatable signatures can be derived than original members of the set were signed. The preferred embodiment, as mentioned earlier and to be described in detail, is believed to have this property in practice, when suitable signature authentication techniques are used, such as when a strong one-way function of suitably large range and domain is used in the signature authentication scheme, as described earlier.

One possible explanation for this property holding is that a set of l signed things can be thought of as giving at most l equations, and these can be solved for at most l unknowns.

Yet another property of a blind signature system will be called the inability to "link", which may be understood as follows. Suppose there are l different messages, m_j for $1 \leq j \leq l$. Each message is the input to a blinding transformation, using key k_j , and the result is l blinded messages t_j . (It is not essential whether each message is blinded by a different party, all messages are blinded by the same party, or various parties each blind some subset of the messages.) Suppose further that the signer applies the signing transformation to each blinded message t_j , and returns each transformed messages t'_j to its provider. Further suppose that each provider applies the appropriate unblinding transformation to each

t'_j , yielding a collection of l unique messages m'_j , each bearing a signature property. Suppose still further that the signer receives an unordered set whose l elements are exactly the m'_j , which may be denoted $\{m'_i\}$ for $1 \leq i \leq l$. Finally, assume that the signer knows only
 5 the l things he has signed, t_j , and the set $\{m'_i\}$, and no outside information about the provider(s), their keys, or information flows from or to the provider(s). The signer can "link" the things received for signing t_j with the things known to have the signature property $\{m'_i\}$, if and only if he can determine with certainty for
 10 every element of $\{m'_i\}$, the unique t_j which corresponds with the same message m , under the assumptions above. If nothing at all can be known about the correspondence, under the assumptions above, not even associating different probabilities with different correspondences, then the blind signature system may be said to be "com-
 15 pletely unlinkable." The term "blinded" may be used to indicate that it is not usually easy to completely link. For example, one m' and one t may be said to be blinded from each other without k , if it can not usually easily be determined without k that the two correspond.

20 In the preferred embodiment, as mentioned earlier and to be described in detail, it is believed to be possible to come close to, or in some cases under certain assumptions even achieve, complete unlinkability. A possible explanation for this might be that for each possible way to put the l items into correspondence, there
 25 could exist a unique set of values for the keys k_j , such that this would be the true correspondence, but assuming each k is chosen so that all values are equally likely, all possible correspondences are equally likely. (Of course the question of actual generation of random numbers from a perfectly uniform distribution is beyond the
 30 scope of the present description.) It is believed that one possible explanation of this may be seen by considering the position of the signer as follows. He has two sets of values: $\{t_j\}$, and $\{m'_i\}$. If he assumes that t_v corresponds with m'_u , then he can determine the

- 15 -

unique k which would have been used to form t_v . This may be accomplished by solving the congruence $t_v \cdot k_v^e \equiv m_u^e \pmod{n}$, for k_v . To do this, one may first compute the multiplicative inverse of m_u modulo n , and assuming that m and n are coprime, as mentioned earlier, there is a unique such value. Then the unique product of this value and t_v is formed, modulo n . Finally, the result is raised to the d power modulo n , producing a unique result, assuming that e is coprime with $\phi(n)$. Thus, under the assumptions, for every possible way the two sets could be linked, there exists unique choices for the keys k_j that would make this the true linking, and, as mentioned above, since the k s are by assumption chosen from a uniform distribution, all such choices for the keys k_j are equally likely, and so all possible linkings are equally likely. This concept is further illustrated by numerical examples as will be presented in the detailed description of the preferred embodiment.

Referring now to FIG. 2, several exemplary modes of use in accordance with the teachings of the present invention will be presented.

FIG. 2a shows a mode of use with only a single cryptographic blinding and corresponding cryptographic unblinding transformation, as mentioned earlier. The message m is transformed by cryptographic blinding transformation 203 into transformed message t , which is input to signature transformation 202, which transformation depends on secret signing information, not shown for clarity. The output of the signing transformation, t' , is input to the unblinding transformation 204, which transformation depends on key k , and which transformation produces output m' , bearing a signature property related to the m . (Notice that blinding transformation 203, signature transformation 202 and unblinding transformation 204 of FIG. 2a correspond with blinding transformation 103, signature transformation 102 and unblinding transformation 104 of FIG. 1, respectively.)

Referring now to FIG. 2b, a first mode of use is shown with two

- 16 -

cryptographic blinding transformations, two cryptographic unblinding transformations, and two separate keys for these transformations. The original message m is transformed by blinding transformation 221, which transformation depends on key k_1 , producing output shown as t_1 , and then supplied as input to blinding transformation 222, which transformation depends on key k_2 , and whose output is shown as $t_{1,2}$. Signing transformation 223 takes this multiply transformed message as input and produces, in a way depending on secret signing information, not shown for clarity, output shown as $t'_{1,2}$. This output is shown as input to unblinding transformation 224, which depends on key k_2 , and produces output shown as t'_1 . This output is input to unblinding transformation 225, which depends on key k_1 , and which produces output shown as m' retaining a digital signature property related to m .

15 In one use of this mode based on the preferred embodiment, described earlier and to be described in detail, the following congruences might hold:

$$t_1 \equiv m \cdot k_1^e \pmod{n},$$

$$t_{1,2} \equiv t_1 \cdot k_2^e \pmod{n},$$

$$t'_{1,2} \equiv t_{1,2}^d \equiv m^d \cdot k_1 \cdot k_2 \pmod{n},$$

$$t'_1 \equiv t'_{1,2} \cdot k_2^{-1} \equiv m^d \cdot k_1 \pmod{n},$$

$$m' \equiv t'_1 \cdot k_1^{-1} \equiv m^d \pmod{n},$$

and the checking function can be based on the congruence

$m'^e \equiv m \pmod{n}$. Thus, the blinding transformation 221 and 225 as well as the unblinding transformation 222 and 224 are each nearly

the same as in the single key mode of the preferred embodiment to be described in detail.

If only a single party with access to both keys k_1 and k_2 uses this mode, then it may be equivalent to a single key use, as in the preferred embodiment. The present mode may have additional benefits, advantages and features, however, in some anticipated applications. Consider the case where one party holds k_1 and a second holds k_2 . Both parties become mutually dependent once the signature transformation has been made: the first party requires the cooperation of the second to transform $t'_{1,2}$ into m' ; similarly, the second party requires the cooperation of the first to transform t'_1 into m' . In the embodiment described above, the second party can check that the signer 223 has performed the proper function, by checking that $t_{1,2} \equiv t'^e_{1,2} \pmod{n}$. The first party is in a position to check the signature function performed by signer 223 by checking that $t_1 \equiv t'^e_1 \pmod{n}$, but this function is also available to the single provider party in a single non-signer party mode of use, but it is anticipated that the signature would normally be checked by the single party by checking that $m \equiv m'^e \pmod{n}$. Notice also that the communication between the second party and signer 223 in the present mode is obscured from the first party. For example, the second party may be second party to several first parties, and they may not know which of the communications with signer 223 include their particular values of m . Similarly, the second party may obscure from the signer which of the communications with first party(s) correspond to particular signature transformations made by signer 223. In some embodiments, such as the preferred embodiment, it may even be the case that cooperation between the first party and signer 223 to determine the correspondence between communications known to one and communications known to the other can be thwarted by the second party.

Of course the present discussion can readily be generalized to

- 18 -

a use based on a plurality of provider parties--not just two or fewer non-signer parties. In a multiple provider party use based on the preferred embodiment: each party performs transformations just as if they were in a single or two non-signer party use as described
 5 herein; parties may readily check that the signature property has been properly applied and transferred by the signer and those parties on the signer's side; and any intermediary party is able to thwart attempted linking even by cooperation of all other parties.

Referring now to FIG. 2c, a second mode of use is shown with
 10 two cryptographic blinding transformations, two cryptographic unblinding transformations, and two keys for these transformations. The original message m is transformed by blinding transformation 231, which transformation depends on key k_1 , producing output shown as t_1 , and then supplied as input to blinding transformation 232,
 15 which transformation depends on key k_2 , and whose output is shown as $t_{1,2}$. Signing transformation 233 takes this multiply transformed message as input and produces, in a way depending on secret signing information, not shown for clarity, output shown as $t'_{1,2}$. This output is shown as input to unblinding transformation 234, which
 20 depends on key k_1 , and produces output shown as t'_2 . This output is input to unblinding transformation 235, which depends on key k_2 , and which produces output shown as m' , retaining a digital signature property.

In one embodiment of this mode of use based on the preferred
 25 embodiment, described earlier and to be described in detail, the following congruences might hold:

$$t_1 \equiv m \cdot k_1^e \pmod{n},$$

$$t_{1,2} \equiv t_1 \cdot k_2^e \pmod{n},$$

$$t'_{1,2} \equiv t_{1,2}^d \equiv m^d \cdot k_1 \cdot k_2 \pmod{n},$$

- 19 -

$$t'_2 \equiv t'_{1,2} \cdot k_1^{-1} \equiv m^d \cdot k_2 \pmod{n},$$

$$m' \equiv t'_2 \cdot k_2^{-1} \equiv m^d \pmod{n},$$

and the checking function can be based on the congruence $m'^e \equiv m \pmod{n}$. Thus, the blinding transformation 231 and 235 as well as the unblinding transformation 232 and 234 are each nearly the same as in the single key mode of the preferred embodiment to be described in detail.

Again, little advantage may result if one party uses two separate keys. The present mode may have additional benefits, advantages and features, however in some anticipated applications. Consider the case where one party holds k_1 and a second holds k_2 , as before. In the earlier described first two provider mode of use, the second party could cheat the first party by simply discarding t_1 and supplying some t_2 of the second parties' choice to signer 223. Then the second party could unblind the resulting t'_2 received from signer 223, and obtain the signature property on something chosen only by the second party, leaving the first party without the expected message bearing the signature property. In the present mode, however, if the signer only signs $t_{1,2}$ when supplied by the second party, and returns the $t'_{1,2}$ only to the first party, then neither party can cheat the other.

Of course both modes shown with two non-signer parties can readily be generalized in combination: a message travels through one permutation of the parties on the way to the signer and through a possibly different permutation on the way back. The no linking property is believed to still hold for any single intermediary party; the no cheating property holds for a party if no cheating party is between the party and the signer in at least one direction.

- 20 -

DETAILED DESCRIPTION OF PREFERRED EMBODIMENT

Turning now to FIG. 1, a detailed description of a preferred embodiment of the present invention is presented. One party to the system will be referred to as the "provider", shown as contained in the dashed box 101. Another distinguished party in the system is the "signer", shown as contained within dashed box 102. A key source for developing a secret key preferably confidential to the provider, is shown contained within the provider 101. A secret signing key, d , is shown contained within signer 102. The provider also contains the ability to perform two transformations. A "blinding" transformation 103 and an "unblinding" transformation 104. A checking function 105 is also shown.

The message m appear on line 151 as one multiplicand input to modular multiplier 121, such multipliers to be described. The other multiplicand input to modular multiplier 121 is from line 152, which is the output of modular exponentiator 122, such modular exponentiators to be described. The base input to exponentiator 122 appears on line 153, and is the key output from key source 123, such key sources described earlier. The exponent, or as used equivalently herein, the powerer input to exponentiator 122 is from line 154, and is the public signature exponent shown as e . The product output of multiplier 121 appears on line 155, which line is the base input to modular exponentiator 124. The exponent to exponentiator 124 is the secret signing key shown as d , which appears on line 156. The output of the exponentiator 124, in this embodiment, is the digital signature of its input base from line 155, and appears on line 157, which is input to modular multiplier 125. The other multiplicand input to multiplier 125 appears on line 158, which is the output of modular inverter 126, such modular inverters to be described. The modular inverter takes its input from the key source 123 mentioned earlier as line 153. The product output of modular multiplier 125 appears on line 159, which is base input to modular exponentiator 127. The power input to exponentiator 127 is shown as e on line

160. The output of exponentiator 127 is shown as m on line 161.

The operation of the preferred embodiment shown in FIG. 1 will now be described in detail. A message m is obtained on line 151 by the provider. A key appears on line 153, denoted as k , preferably
 5 secret to the provider, is developed by key source 123, and is preferably chosen from the interval 0 to $n-1$ with each value as nearly equally likely as practical. The blinding transformation 103 takes these two inputs, lines 151 and 153, and forms a blinded message denoted as t on its output line 155, such that
 10 $t \equiv m \cdot k^e \pmod{n}$. These functions of the blinding transformation 103 are accomplished as follows. Modular exponentiator 122 takes the key k as its base input from line 153 and takes the public signature key e from line 154, and outputs on line 152 a value congruent modulo n to k^e . Modular multiplier 121 takes this value
 15 from line 152 and forms the modulo n product with the input m from line 151, and the product output appears on line 155.

Now the signer 102 may obtain the blinded message t from line 155, and will normally output a digital signature of t on line 157, the output denoted as t' , such that $t' \equiv t^d \pmod{n}$, where d is the
 20 secret signing exponent of the signer mentioned earlier. These functions of the signer 102 are accomplished as follows. Modular exponentiator 124 takes its base input from line 155, takes its power input from line 156, and its output appears on line 157.

Now the provider may perform the unblinding transformation,
 25 shown as 104. The output of the signer, t' , and the secret key k are inputs to this function and it produces, in this embodiment, a digital signature on m , denoted m' , such that $m' \equiv m^d \pmod{n}$. This function of the unblinding transformation is performed as follows. The multiplicative inverse of the secret key k is formed by the
 30 modular inverter 126. Then the product modulo n of the multiplicative inverse, shown as k^{-1} , and the signed blinded message t' from line 157 is formed by modular multiplier 125, and its output appears

on line 159.

At some latter time, one or more parties may wish to check or authenticate the digital signature m' on the original message m .

This function may be performed by checking that $m \equiv m'^e$, and that m is a valid message, as described earlier. This function can be performed by the modular exponentiator 127, which takes its base input from line 159 and its power from line 160, and whose output appears on line 161. A specific example of further checking for valid messages or the like is not shown for clarity, but such techniques would be obvious from the earlier description, and are well known to those of ordinary skill in the art. For example, the binary representation of the value on line 161 could be split into two halves, and the number considered valid if the result of comparing the two halves indicates they are identical.

The following table illustrates the operation of one use of the preferred embodiment by associating the various line numbers in the first row and their symbolic names in the second, with the exemplary values in the remaining nine data rows. The table uses an RSA system based on primes 29 and 31 chosen by the signer. The modulus made public by the signer would then be $n=29 \cdot 31 = 899$. The signer is assumed to have chosen e to be 17, (possibly after checking that $\text{GCD}(17, \phi(n))=1$) and computed its multiplicative inverse modulo $\phi(n)=(29-1) \cdot (31-1)=840$, and with the result $d = 593$. Of course such a system is based on numbers far too small to be secure. (Finding k^{-1} for the value of k in the first data row is the subject of an example of the operation of the modular inverter to be described.) Notice that the first and second data rows have the same t values as the penultimate and last data rows respectively, but that their messages m are interchanged with different values of k , as mentioned earlier.

| | 151 m | 153 k | 152 k^e | 155 t | 157 t' | 158 k^{-1} | 159 m' |
|----|----------|----------|--------------|----------|-------------|-----------------|-------------|
| 5 | 628 | 255 | 886 | 826 | 19 | 691 | 543 |
| | 254 | 685 | 84 | 659 | 698 | 21 | 274 |
| | 40 | 393 | 210 | 309 | 340 | 716 | 710 |
| | 153 | 440 | 212 | 72 | 541 | 615 | 85 |
| | 755 | 748 | 16 | 393 | 110 | 256 | 291 |
| 10 | 623 | 111 | 107 | 135 | 601 | 81 | 135 |
| | 724 | 308 | 461 | 235 | 69 | 108 | 260 |
| | 254 | 548 | 520 | 826 | 19 | 251 | 274 |
| | 628 | 94 | 807 | 659 | 698 | 373 | 543 |

Referring now to FIG. 3, a detailed description of an exemplary embodiment of a modular multiplicative inverter, herein called a modular inverter, is presented. The number to be inverted appears on line 351, and is initially loaded into register 301. The output of register 301 appears on line 352, which is input to register 302, which takes its initial value, the modulus n , from line 353, and has output on line 354. Ordinary arithmetic divider 303, takes its dividend from line 354 and its divisor from line 352, its quotient output appears on line 355 and its remainder output appears on line 356. Such binary arithmetic dividers for unsigned integers are well known in the art, for example see K. Hwang, "Computer Arithmetic: principles, architecture, and design" John Wiley, 1979, Chapter 7. Line 356 is input to register 301, described earlier. Line 355 is input to modular multiplier 304, such multipliers to be described. The output of modular multiplier 304 is line 357, which is subtrahend input to modular subtractor 305, such subtractors to be described. The difference output of modular subtractor 305 is line 358, which is input to register 306, which takes its initial value of 1 from line 359 and whose output appears on line 360. Modular multiplier 304 already described takes one of its multiplicand inputs from line 360. Register 307 takes input from line 360, takes

its initial value of 0 from line 361, and its output appears on line 362. Line 362 is minuend input for modular subtractor 305 already described, and is the output of the modular inverter.

A detailed description of the operation of the modular inverter
5 of FIG. 3 is now presented. The modular inverter takes an input
from line 351 whose value is between 0 and $n-1$, and produces on the
output line 362 a value between 0 and $n-1$ which is congruent to the
multiplicative inverse modulo n of the value input. The principle
of operation is based on a variation of Euclid's algorithm, and is
10 well known in the art. See Knuth, D.E., "The Art of Computer Pro-
gramming: Volume 2/ Seminumerical Algorithms," Addison-Wesley, 1969,
Euclid's algorithm, page 297, exercise 4.5.2 #15 on page 315, and
answer to exercise 4.5.2 #15 on page 523. Initially register 302
contains n , register 301 contains the input from line 351, register
15 306 contains 1, and register 307 contains 0. The operation proceeds
synchronously by clock pulses sufficiently spaced to allow all lines
to settle between pulses. Clock pulses occur until the first time
that the contents of register 301 are 0. The clock and associated
lines, as well zero detector for register 301, are not shown for
20 clarity, but would be obvious to those skilled in the art from the
present description. Before the first clock pulse and after each
clock pulse, divider 303 divides the contents of register 302 by the
contents of register 301 and supplies the quotient to modular multi-
plier 304 and the remainder to the input to register 301. Once the
25 quotient value settles, modular multiplier 304 forms the modulo n
product of the quotient and the contents of register 306, and sup-
plies the product as the minuend input to modular subtractor 305.
Once the product value settles, modular subtractor 305 subtracts
modulo n the product from the contents of register 307 and supplies
30 the difference to an input of register 306. With the rising edge of
each clock pulse, register 302 latches in new contents from line
352, and register 307 latches in new contents from line 360. During
the falling edge of each clock pulse, register 301 latches in new
contents from line 356, and register 306 latches in new contents

from line 358. The duration of each clock pulse is short enough that the output of modular subtractor 305 and the remainder output 356 of divider 303 do not change between the rising and falling edge of a clock pulse.

5 The following table illustrates the operation of the modular inverter by showing the contents of the various registers at the end of each cycle. Cycles #0 shows the initial state; and as can be seen from the first row, the number whose inverse is sought is 255, initially in register 301; and the modulus n is 899, initially in
10 register 302. As can be seen from the row of cycle #6, the result in register 307 is 691.

| | | register number | | | |
|----|----|-----------------|-----|-----|---------|
| | | cycle | 301 | 302 | 306 307 |
| 25 | 15 | #0 | 255 | 899 | 1 0 |
| | | #1 | 134 | 255 | 896 1 |
| | | #2 | 121 | 134 | 4 896 |
| | | #3 | 13 | 121 | 892 4 |
| | | #4 | 4 | 13 | 67 892 |
| 30 | 20 | #5 | 1 | 4 | 691 67 |
| | | #6 | 0 | 1 | 0 691 |

Turning now to FIG. 4, a detailed description of an exemplary embodiment of a modular exponentiator is presented for completeness. The base input appears on line 451, which is an initial input to
35 register 401. The output of register 401 appears on line 452, which is both multiplicand inputs to modular multiplier 402, to be described. The output of modular multiplier 402, line 453, is an data input to register 401. The output of register 401, line 452, is one multiplicand input to modular multiplier 403. The product
40 output of modular multiplier 403 appears on line 454 and is a data input for register 404. The initial value for register 404 is 1 and is shown on line 455. The contents of register 404 appear on line

456, which is input to modular multiplier 403 and also output of the modular exponentiator. The exponent input appears on line 457 and is initial data input for ordinary right shifting binary shift register 405. The rightmost bit of shift register 405 appears as its output on line 458, which line enables the latching function of register 404, to be described.

A detailed description of the operation of the exemplary modular exponentiator of FIG. 4 is now presented. The modular exponentiator takes two inputs, a base from line 451 (represented as a value between 0 and $n-1$) and a power from line 457 (a positive binary integer), and produces on its output line 456 a value between 0 and $n-1$ that is congruent modulo n to the base raised to the power. The principle of operation is to form the product of the base raised to all powers of two that correspond with set bits in the exponent. (For example, notice that $21 = 2^0 + 2^2 + 2^4$, and $5^{21} = 5 \cdot 5^{2^2} \cdot 5^{2^4} = 476837158203125$.) Initially, the base and exponent are in registers 401 and 405 respectively, and register 404 is reset to one. The operation proceeds in l cycles, where l is the number of bits used to represent numbers between 0 and $n-1$. At the end of each of the l cycles a clock line (not shown for clarity) is raised briefly from the zero state to the one state and then returned to the zero state. During the first cycle, the contents of register 401 is squared (modulo n) by modular multiplier 402 and appears on line 453, and the modulo n product of the content of register 401 and register 404 is developed by modular multiplier 403 and appears on line 454. At the end of the first cycle, on the rising edge of the first clock pulse, the value on line 453 is latched into register 401, the value on line 454 is latched into register 404 only when the enabling value on line 458 is a one bit, and on the falling edge of the clock the contents of register 405 is shifted one bit to the right. During each of the $l-1$ subsequent cycles, the new products settle on lines 453 and 454, and at the end of the cycle, with the rising edge of the clock, the value on line 453 is latched into register 401, and the value on line 454 is

- 27 -

latched into register 404 if and only if line 458 has the enabling value of a one bit, and with the falling edge of the clock, the contents of register 405 is shifted one bit to the right. Thus, after the fall of the clock pulse 1, the last clock pulse, all the original bits of register 405 have been shifted out, register 401 contains a number congruent modulo n to the value on line 451 squared 1 times, and the content of register 404 is the desired value and is on the output line 456 of the modular exponentiator.

Referring now to FIG. 5, a detailed description of an exemplary embodiment of a modular multiplier is presented for completeness. One multiplicand input appears on line 551, which is an input to register 501. The output of register 501 appears on line 552, which is both addend inputs to modular adder 502, to be described described. The output of modular adder 502, line 553, is an input to register 501. The output of register 501, line 552, is one addend input to modular adder 503. The sum output by modular adder 503 appears on line 554 and is a data input for register 504. The initial value for register 504 is 0 and is shown on line 555. The contents of register 504 appear on line 556, which is input to modular adder 503 and also output of the modular multiplier. The second multiplicand input appears on line 557 and is data input for ordinary right shifting binary shift register 505. The rightmost bit of shift register 505 appears as its output on line 558, which line enables the latching function of register 504, to be described.

A detailed description of the operation of the exemplary modular multiplier of FIG. 5 is now presented. The modular multiplier takes two multiplicands, one from each of lines 551 and 557, each represented as a value between 0 and $n-1$, and produces on its output line 503 a value between 0 and $n-1$ that is congruent modulo n to the product of the multiplicands. The principle of operation is to form the sum of one multiplicand multiplied by all powers of two that correspond with set bits in the other multiplicand. (Notice, for example, that $21 = 2^0 + 2^2 + 2^4$, and

$13 \cdot 21 = 13 \cdot 2^0 + 13 \cdot 2^2 + 13 \cdot 2^4 = 273$.) Initially, the

multiplicands are in registers 501 and 505, and register 504 is
 reset to zero. The operation proceeds in l cycles, where l is the
 number of bits used to represent numbers between 0 and $n-1$. At the
 end of each of the l cycles a clock line (not shown for clarity) is
 5 raised briefly from the zero state to the one state and then
 returned to the zero state. During the first cycle, the contents of
 register 501 is doubled (modulo n) by modular adder 502 and appear
 on line 553, and the modulo n sum of the content of register 501 and
 register 504 is developed by modular adder 503 and appears on line
 10 554. At the end of the first cycle, on the rising edge of the first
 clock pulse, the value on line 553 is latched into register 501, the
 value on line 554 is latched into register 504 only when the ena-
 bling value on line 558 is a one bit, and on the falling edge of the
 clock the contents of register 505 is shifted one bit to the right.
 15 During each of the $l-1$ subsequent cycles, the new sums settle on
 lines 553 and 554, and at the end of the cycle, with the rising edge
 of the clock, the value on line 553 is latched into register 501,
 and the value on line 554 is latched into register 504 if and only
 if line 558 has the enabling value of a one bit, and with the fal-
 20 ling edge of the clock, the contents of register 505 is shifted one
 bit to the right. Thus, after the fall of the l th (final) clock
 pulse, all the original bits of register 505 have been shifted out,
 register 501 contains a number congruent modulo n to the value on
 line 551 doubled l times, and the content of register 504 is the
 25 desired value and is on the output line 556 of the modular multi-
 plier.

Referring now to FIG. 6, a detailed description of an exemplary
 embodiment of a modular subtractor is presented for completeness.
 The subtrahend to the modular subtractor is on line 651 which is the
 30 subtrahend to ordinary arithmetic subtractor 601, such ordinary
 arithmetic binary subtractors with positive integer inputs being
 well known in the art. The minuend input to subtractor 601 is on
 line 652 and is the modulus n . The result of the ordinary subtrac-
 tor 601 appears on line 653. Modular adder 602, to be described,

- 29 -

takes the difference from line 653 and the minuend for the modular subtractor from line 654, and produces the modulo n sum as its output on line 655.

The detailed operation of the modular subtractor of FIG. 6 is now described. Its inputs are numbers between 0 and $n-1$ and it produces a number between 0 and $n-1$ which is congruent to the difference of the input numbers modulo n . A number congruent to the additive inverse modulo n of the subtrahend from line 651 is developed by subtractor 601, by subtracting from n , and transmitted by line 653 to modular adder 655, and then added modulo n to the minuend on line 654, producing the result on line 655.

Referring now to FIG. 7, a detailed description of an exemplary embodiment of a modular adder is presented for completeness. The two numbers to be added are supplied on lines 751 and 752, which are the summand inputs to ordinary binary adder 701, such ordinary binary arithmetic adders being well known in the art. The output of adder 701 is supplied by line 753 to the subtrahend input to ordinary binary subtractor 702. The minuend supplied subtractor 702 on line 754 is the modulus n for the modular addition. The result of the ordinary subtraction by subtractor 702 appears on line 755. Ordinary binary comparator 703, such comparators being well known in the art, takes one comparend input from line 753 and the other comparend from line 756, which is the modulus n , and develops a single output bit indicating the result of the comparison, which output appears on line 757. Selector 704 takes its two data inputs from lines 755 and 753, and its control input from line 757, has output on line 758, the output of the modular adder, and outputs data from line 753 if comparator output 757 indicates that data value on line 753 is less than the data value on line 756, and outputs data from line 755 otherwise.

The operation of the exemplary modular adder of FIG. 7 will now be described in detail. The modular adder takes two numbers between 0 and n , not both n , and produces as output a third numbers between

- 0 and $n-1$ which is congruent to the sum of the inputs modulo n . Two numbers to be added modulo n appear on lines 751 and 752 and are added by ordinary arithmetic producing a sum on line 753. The sum is subtracted from n by subtractor 702 with the result on line 755.
- 5 The sum is compared with n by comparator 703, with the result on line 757. If the comparison indicates that the sum is less than n then the sum is between 0 and $n-1$ and is output on line 758; otherwise the sum is at most n too large, and the difference of the sum and n from line 755 is output on line 758.
- 10 While these descriptions of the present invention have been given as examples, it will be appreciated by those skilled in the art that various modifications, alternate configurations and equivalents may be employed without departing from the spirit and scope of the present invention.

Claims:

1. In digital signature cryptographic apparatus, the improvement characterized by blind signature systems comprising:
first transformation means responsive to a first key taking a first
5 input and producing a first output hiding the first input from those without the first key;
digital signature means for transforming said first output responsive to a second secret key and producing a second output; and
second transformation means for transforming said second output,
10 responsive to said first secret key, producing a third output, while preserving a digital signature property related to said first input and said first output not readily linkable to the third output without the first secret key.
2. In digital signature cryptographic apparatus, the improvement characterized by blind signature systems comprising:
15 key source means for developing a first key for use by a first party, said first key normally at least secret from a second party;
first cryptographic transformation means allowing said first party
20 to transform a message depending at least in part on said first secret key and rendering said message not readily recognizable without said first key;
first communication means for transmitting said transformed message from said first cryptographic transformation means of said
25 first party to said second party;
digital signature means allowing said second party to develop a digital signature responsive to said transformed message received from said first communication means depending at least in part on a signing key, said signing key normally at
30 least secret from said first party;
second communication means for transmitting said digital signature from said digital signature means of said second party to said first party; and

second cryptographic transformation means depending at least in part on said first secret key allowing said first party to transform a digital signature of said transformed message received from said second communication channel into a digital signature relating to said message and not readily distinguishable without said first key as resulting from a particular said transformed message.

3. In the apparatus of claims 1 & 2, first transformation means, signing transformation means, and second transformation means, such that said third output equivalent to output of said signing means if said message input to said signing means.

4. In the apparatus of claims 1 & 2, first transformation means including means for developing residue modulo the public modulus of multiplication by the first key raised to a public signing power; signing transformation means including means for developing residue modulo the public modulus of exponentiation to a power depending on the signing key; and and second transformation means including means for multiplying by the multiplicative inverse of the first key modulo the public modulus.

5. In the apparatus of claims 1 & 2, first transformation means such that there almost always exists some first key that would cause the first transformation of any particular message to be any particular transformed message.

6. In the apparatus of claims 1 & 2, key source means for choosing said first key from a distribution making almost every pair of messages resulting from said first and second transformations nearly equally likely to correspond.

7. In the apparatus of claims 1 & 2, key source means for choosing said first key from a nearly uniform distribution and first and second transformation means such that there almost always exists

- 33 -

a unique first key that would cause the first transformation of any particular message to be any particular transformed message.

8. Blind signature apparatus as described in claims 1 & 2,
such that said first transformation means having input signals m and
5 first key k and producing output signals described by

$$t \equiv m \cdot k^e \pmod{n}$$

where e = a public signing exponent, and n = a public signature modulus;

10 said signing transformation means having input signals t and secret signing key d and producing output signals t' described by

$$t' \equiv t^d \pmod{n}; \text{and}$$

said second transformation means having input signals t' and first key k and producing output signals m' described by

$$m' \equiv m^d \pmod{n}.$$

15 9. In a digital signature cryptographic method, with a first party supplying messages to a second party who returns to the first party a digital signature on supplied messages, the improvement comprising blind signature systems characterized by the steps of:
generating a first secret key at the first party, said key normally
20 at least unknown to said second party;
transforming a message with said first secret key, producing a first transformed message;
transmitting said first transformed message to said second party;
forming a digital signature of said first transformed message with a
25 secret signing key, said secret signing key normally not known to said first party;
transmitting said digital signature from said second party to said

first party; and
transforming said digital signature at said first party with said
first secret key producing a second transformed message, such
that said first transformed message and the second transformed
5 message are not readily determined to correspond without
knowledge of said first secret key, and the second transformed
message bearing a digital signature property related to said
message.

10. In a digital signature method, the improvement comprising
10 a blind signature cryptographic method characterized by the steps
of:

transforming an original message with a first secret key;
forming a digital signature of said transformed message;
transforming said signed transformed message with said first secret
15 key, such that a digital signature related to the original
message results, and the correspondence between the signed
message and the first transformed message is not obvious
without said first secret key.

11. In the method of claim 9 & 10, choosing said first secret
20 key such that almost every result of the first transformation step
could correspond with almost every result of the second transforma-
tion step with nearly equal likelihood.

12. In the method of claim 9 & 10,
first transformation step of the message with the first key includ-
25 ing forming the product of the first key raised to the public
signing power and the message modulo the public signing
modulus;

signing step including raising the transformed message to the secret
signing exponent modulo the public signing modulus; and
30 second transformation step including forming the multiplicative
inverse of the first key modulo the public signing modulus and
forming the product of this with the result of the signing
step.

13. In cryptographic apparatus, the improvement comprising a blind signature system comprising:
first blinding means for transforming a message responsive to a first secret key producing a first output;
5 second blinding means for transforming output of said first blinding means responsive to a second secret key producing a second output;
digital signature means for developing a digital signature related to said second output, responsive to a secret signing key;
10 first unblinding means for transforming said digital signature, responsive to a first one of said first and second secret keys, producing a third output; and
second unblinding means for transforming said third output, responsive to a second one of said first and said second secret
15 keys, producing a fourth output, and the fourth output having a digital signature property related to said message, and said first output and said fourth output not readily linkable without both the first and the second secret keys.

14. In a digital signature cryptographic method, the improvement comprising a blind signature method comprising the steps of:
20 transforming a message with a first blinding transformation depending on a first secret key, producing a first output;
transforming said first output with a blinding transformation depending on a second secret key, producing a second output;
25 developing a digital signature related to said second output depending on a secret signing key;
transforming said digital signature with a first unblinding transformation, depending on a first one of said first and said second secret keys, producing a third output; and
30 transforming said third output with an unblinding transformation, depending on a second one of said first and second secret keys, producing a fourth output retaining a digital signature property related to said message, and said first and fourth output not readily determined to correspond without the first
